Adrenals and Stress Hormones

Dave Bridges, Ph.D.

March 23, 2016

This lecture covers the role of the adrenal glands. The major topics covered will be the regulation of salt balance by aldosterone and stress responses mediated by adrenal gland secretions. This lecture covers the following pages in the textbook: 169, 321,326, 344-349, 394-5, 514-5 and 583[1].

Contents

Learning Objectives

For this lecture, the learning objectives are:

- Name three zones in the adrenal cortex and major regulator(s) of each zone.
- Name three steroidogenesis pathways and their major products.
- Explain briefly the physiological mechanism of adrenogenital syndrome.
- Describe the physiological actions and roles of aldosterone.
- Explain briefly the renin-angiotensin system.
- Describe the negative feedback regulation of aldosterone and its relationship to blood volume/blood pressure homeostasis.
- Describe hepatic and extrahepatic metabolic actions of glucocorticoids. Discuss their relationship.
- State the major findings caused by adrenal hypersecretion of mineralocorticoids.
- State the major findings caused by adrenal hypersecretion of glucocorticoids.
- Name the major hormones secreted from the adrenal medulla. Discuss the differences of epinephrine (epi) and norepinephrine (NE) in cardiovascular actions (physiological levels).
- List the major metabolic actions of catecholamines.
- Contrast the thresholds for actions vs. plasma levels of epi and NE under common conditions, like exercise, and in the disease pheochromocytoma

Anatomy of the Adrenal Gland

The adrenal gland is located above the kidney and releases hormones in response to either nervous or hormonal stimulation. The central part of the adrenal gland, known as the adrenal medulla releases epinephrine and norepinephrine which are biogenic amines. The three regions of the adrenal medulla[2] release steroid hormones including aldosterone[3], cortisol[4], and androstenedione (see Figure 1). These pathways all initiate from cholesterol, but involve activation of different enzymes to generate these chemically similar, but functionally distinct steroid hormones.

[2] zona glomerulosa, zona fasciculata and zona reticularis
[3] a mineralcorticoid
[4] a glucocorticoid

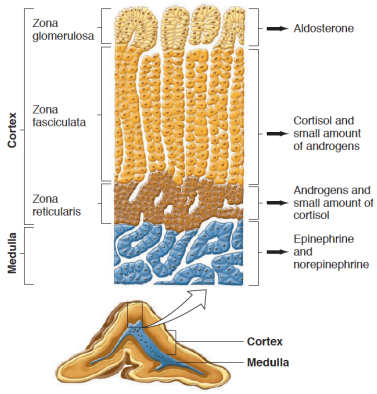

Figure 1: The anatomy of the adrenal gland.

Steroid Hormones Secreted from The Adrenal Gland

Specific steroid hormones are synthesized from cholesterol via enzymes which are regulated by GPCR mediated signaling[5]. Since steroid hormones are membrane soluble they can be released from the cell. They move through the serum bound to proteins called globulins which maintain solubility in the blood stream before they passively cross into other tissues. Both aldosterone and cortisol signal via nuclear hormone receptor signaling mechanisms in their target cells. These steroid hormones have different receptors which activate different genes.

[5] ACTH for cortisol; Angiotensin II for aldosterone

Aldosterone

Aldosterone, a mineralcorticoid is responsible for sensing and modulating salt balance at the kidney. It is produced in the adrenal cortex in a region called the zona glomerulosa. The main site of action of aldosterone is the cortical collecting ducts and the distal convoluted tubule, where it functions to stimulate sodium re-absoroption.

The mineralcorticoid receptor binds to aldosterone, which then promotes the transcription of several important genes involved in salt re-uptake in the kidney. These include:

Sodium/potassium pumps. These pumps exchange sodium for potassium, to move sodium out of the kidney and back into the blood. This is an active transport mechanism, requiring ATP which transports both ions across their concentration gradients.

ENac This is a sodium transporter that also helps get sodium from the tubule into the cells of the collecting duct.

Together these genes when activated by aldosterone enhance the movement of sodium ions out of the kidney tubule and back into

the blood stream. This change of osmotic balance also promotes the flow of water back into the blood via aquaporins, a process that is also under the control of vasopressin, as we covered on the lecture on the posterior pituitary. In the absence of aldosterone, the human body would secrete about 35g of sodium chloride per day. When aldosterone levels are high (due to reduced sodium concentration), nearly all tubular sodium is reabsorbed. The control of aldosterone production requires integration of information about blood volume, blood pressure and sympathetic activity. This integrated endocrine circuit is known as the renin/angiotensin system.

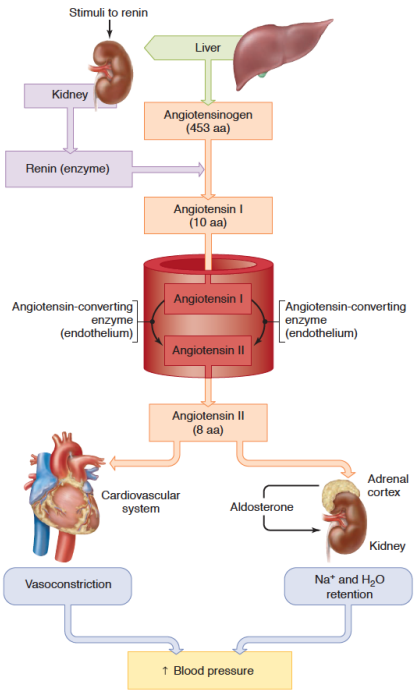

Figure 2: The renin/angiotensin system.

As part of the Reinin-Angiotensin system, the peptide hormone angiotensin II[6] is generated by the liver as a precursor molecule called angiotensinogen. This molecule is processed in two stages to generate angiotensin II (see Figure 2). The first, and most important regulatory step is mediated by a secreted enzyme known as renin. Renin is secreted from specialized pericytes near the kidney glomerulus known as juxtaglomerular cells[7]. When JG cells sense *decreased* stretch (decreased blood pressure), or have elevated sympathetic nervous activity, Renin is released. Renin enzymatically converts angiotensinogen to angiotensin I, which in turn is converted to angiotensin II by angiotensin converting enzyme. In this way, signaling to JG cells can cause increased angiotensin.

[6] the active form

[7] JG cells, see Tigyi lectures for more information

Angiotensin II elevations results in increased smooth muscle vasoconstriction[8] via direct effects on Gq coupled angiotensin receptors[9]. Angiotensin II promotes increased salt reuptake both indirectly via stimulating the synthesis of aldosterone. This pathway is illustrated in Figure 2. Once salt balance, blood volume and blood pressure are renormalized, renin release is reduced[10], causing less angtiotensin I formation and therefore less aldosterone production.

[8] see lectures from O'Connell, Mancarella and Adebiyi

[9] This is the same mechanism by which Gq coupled α_1 adrenoreceptors promote vasoconstriction of smooth muscle feeding the gut, brain and kidneys, as discussed below

[10] because with increased flow to the kidneys, JG cells are re-stretched

Cortisol

Cortisol is synthesized and released from the zona fasciculata in response to stimulation by ACTH[11]. As described previously in the lecture on the anterior pituitary, ACTH is released from the corticotrophic cells of the pituitary in response to the hypothalamic hormone CRH. Cortisol is elevated under times of psychological stress and is also under the control of a circadian cycle[12]. Cortisol levels are normally highest in the morning, reaching a peak shortly before waking up and decline during the day. In addition to psychological stress, cortisol is also elevated in response to prolonged fasting, as we will discuss in the lecture on the pancreas and glucose homeostasis.

[11] Adrenocorticotropic hormone

[12] biological process that displays an endogenous, entrainable oscillation of about 24 hours. For more information see `http://en.wikipedia.org/wiki/Circadian_rhythm`

Night shift workers, such as those as the FedEx facility often have altered circadian rhythms and elevated Cortisol levels. This predisposes people who have abnormal circadian rhythms to have higher risk of diabetes, cardiovascular disease and sleep disturbances[13]. Generally, cortisol functions to shift resources[14] towards essential survival processes, and away from non-essential processes such as growth, reproductive function and immune responses.

[14] mainly glucose

The primary role of cortisol is to maintain blood glucose in times of chronic stress. Since most tissues, including the brain, require glucose but do not store large amounts of glycogen and lipids they require a stable supply of glucose from the periphery. Glucose can be released from liver glycogen stores, or produced from precursor molecules[15] in the liver via a process known as gluconeogenesis. Cortisol, through its nuclear hormone receptor the glucocorticoid receptor, activates the transcription of several important gluconeogenic genes in the liver including PEPCK[16], Pyruvate carboxylase, Glucose-6-phosphatase. To ensure that sufficient precursors are available for hepatic gluconeogenesis, cortisol also activates the breakdown of muscle protein[17] and adipose triglycerides[18]. Finally, cortisol induces resistance to insulin in muscle, adipose and liver tissues. Normally, insulin functions to pull glucose out of the

[15] amino acids and fatty acids

[16] Phosphoenolpyruvate carboxykinase

[17] this is known as proteolysis

[18] this is known as lipolysis

blood and into muscle and adipose tissue, but cortisol prevents this, in order to maintain glucose levels in the blood. The end result of this is that there is increased availability of glucose for the nervous, cardiovascular and respiratory systems.

A SECOND MAJOR ROLE OF CORTISOL IS TO SUPPRESS IMMUNE FUNCTION. Immune responses are energetically quite costly, so in line with directing nutrients to the brain during stress, immune function is decreased. Cortisol functions at several steps in the immune response, including suppressing both the innate and adaptive immune system. This is one of the reasons that cortisol, cortisone, dexamethasone or prednisone[19] are widely used as in autoimmune diseases such as asthma, arthritis and allergic disorders[20].

[19] synthetic glucocorticoids

[20] Think about some of the side-effects of this kind of treatment on musculature and metabolism

IN ADDITION TO ITS DIRECT EFFECTS, CORTISOL ALSO SENSITIZES TISSUES TO EPINEPHRINE, so that short-term stress responses can also be activated in times of chronic stress. This is accomplished by the glucocorticoid receptor directly activating the transcription of the β-adrenoreceptor gene[21]. This is one of several examples we will see over the next few lectures whereby hormones can control sensitivity and responses of other hormonal cascades.

[21] J R Hadcock and C C Malbon. Regulation of beta-adrenergic receptors by "permissive" hormones: glucocorticoids increase steady-state levels of receptor mRNA. *Proceedings of the National Academy of Sciences of the United States of America*, 85(22):8415–8419, 1988. ISSN 0027-8424. DOI: 10.1073/pnas.85.22.8415

LOCAL CONCENTRATIONS[22] OF CORTISOL are regulated by an enzyme known as 11β-hydroxysteroid dehydrogenase 2. This enzyme serves two important roles. One is to allow for local (tissue-specific) negative feedback of the cortisol signal. The other role of 11β-hydroxysteroid dehydrogenase 2 is to prevent tissues that should respond to aldosterone from accidentally responding to elevated levels of the chemically similar cortisol[23]. By elevating 11β-hydroxysteroid dehydrogenase 2 activity, cortisol is converted to cortisone which has less affinity for the glucocorticoid receptor. The inverse enzyme, which converts cortisone back to cortisol is called 11β-hydroxysteroid dehydrogenase 1. This enzyme is typically epxressed in tissues that want to respond to cortisol such as fat, liver and muscle. In some tissues 11β-hydroxysteroid dehydrogenase 1 is actually induced by glucocorticoids causing a *positive feedback loop* to sustain local glucocorticoid effects[24].

[22] i.e. intracellular concentrations

[23] This is a problem, because cortisol and aldosterone are quite similar chemicaly, and at high levels, cortisol can activate the mineralcorticoid receptor.

[24] This makes 11β-hydroxysteroid dehydrogenase 1 inhibitors attractive drug targets that might be useful to minimize some of the long term complications of excessive glucocorticoid elevations

ANOTHER NEGATIVE FEEDBACK MECHANISM FOR CORTISOL IS that elevated cortisol levels suppress the release of both CRH (from the hypothalamus) and ACTH (from the anterior pituitary). This integrated circuit is known as the HPA[25] axis. Any disfunction in negative feedback of the HPA axis can lead to inappropriate overproduction of cortisol, which can be the case in pharmacological

[25] hypothalamus-pituitary-adrenal

administration of glucocorticoids, or tumors that secrete ACTH or cortisol.

Epinephrine and Norepinephrine

In contrast to the steroid hormones described above, the adrenal medulla secretes epinephrine and norepinephrine[26], two water soluble biogenic amines[27]. The adrenal medulla primarily produces epinephrine due to high levels of the enzyme phenylethanolamine-N-methyltransferase. In contrast to cortisol release, which is in response to stress-induced increases in CRH/ACTH, adrenaline is released after direct sympathetic activation innervation of the adrenal medulla. This means that adrenaline levels in the blood are increased quickly and results in much more rapid responses than cortisol.

[26] also known as adrenaline and noradrenaline

[27] also known as catecholamines

THE CIRCULATING LEVELS OF NOREPINEPHRINE ARE LOW, relative the the amount needed to elicit an adrenergic response. This is because in many cases, norepinephrine is utilized synaptically where the local concentrations can be very high. Under most physiological conditions including hypoglycemia or moderate exercise, norepinephrine levels do not rise in the plasma to a level which would activate the adrenergic receptors. The two situations where this may occur are during very heavy exercise or tumors which secrete norepinephrine[28]. For this reason, most acute stress related responses are mediated by epinephrine, not norepinephrine.

[28] Pheochromocytomas, discussed below

EPINEPHRINE BINDS TO α AND β-ADRENERGIC RECEPTORS which are both GPCRs. These are summarized in Table 1. β-adrenergic receptors are coupled to Gs and their activation results in activation of the cAMP/PKA pathways which cause vasodilation of the smooth muscle feeding the skeletal muscles. α-adrenergic receptors are coupled to Gi, which inhibit PKA signaling or Gq proteins which activate IP_3/Ca^{2+} signaling. This is the molecular basis by which adrenaline can cause vasoconstriction in some smooth muscle cells, but vasodilation in others.

Receptor	G-Protein
α_1	G_q
α_2	G_i
β_{1-3}	G_s

Table 1: Adrenergic receptor subtypes and associated G-proteins.

The Role of Biogenic Amines in Cardiovascular Function

One major effect of catecholamine release is to increase blood flow to the muscle, as part of the flight or fight response[29]. This is accomplished by causing more heart muscle contraction (via β-adrenergic receptors linked to Gs in the heart) while also causing vasodilation of the blood vessels feeding the muscle (via α-adrenergic receptors linked to Gs in the blood vessels feeding the muscle tissue). This is

[29] This was covered in more detail by in the lectures given by Drs Mancarella and O'Connell

the molecular basis of using beta-blockers[30] to reduce blood pressure and manage cardiac arrhythmias. At the same time, Gi/Gq-linked receptors in the smooth muscle within the GI tract, kidneys and brain are activated causing vasoconstriction. Together this forces blood (and nutrients) towards the muscle.

[30] β-adrenergic receptor antagonists such as propranolol

Metabolic Effects of Epinephrine

In addition to its cardiovascular effects, much like cortisol, adrenaline functions to make more blood glucose available in times of acute stress. However, in contrast to the slower acting cortisol, adrenaline promotes rapid breakdown of glycogen and triglycerides to make their products available for muscle oxidation[31]. This is also a functional contrast, in that adrenaline is trying to supply glucose to the muscle, while cortisol is trying to supply glucose to the brain[32].

[31] useful when running away from a bear.

[32] useful when living in bear infested woods.

In the liver, where most of the body's glycogen is stored, β-adrenergic receptor activation of cAMP/PKA results in the activation of glycogen phosphorylase[33] and inhibits glycogen synthase. PKA also induces gluconeogenesis like cortisol, but while cortisol only transcriptionally activates gluconeogenic enzymes, PKA phosphorylates an enzyme called PFK-2[34] to induce gluconeogenesis, while also phosphorylating and activating a transcription factor called CREB, in order to transcriptionally increase the levels of gluconeogenic genes.

[33] the enzyme that breaks glycogen down

[34] phosphofructokinase-2, a negative regulator of gluconeogenesis that is inhibited by PKA. This is akin to removing a brake on a process, thereby activating it.

In muscle tissue, PKA activation via a Gs linked β-adrenergic receptor induces glycogenolysis, glycolysis[35] and mitochondrial respiration to generate ATP for muscle contraction. This is in contrast to the liver, where glycolysis *is not activated*, but instead the glucose is produced and released to the muscle for oxidation[36]. In adipose tissue, epinephrine results in rapid induction of lipolysis by PKA-mediated phosphorylation of triglyceride breakdown enzymes. These fatty acids are then also oxidized for energy in muscle tissue or used as gluconeogenic substrates in the liver. β-adrenergic receptor agonists have therefore been proposed to be weight loss drugs, but the cardiovascular side effects[37] have limited their usefulness.

[35] glucose breakdown into ATP

[36] Think about how this could be achieved, once you have learned how glucagon affects muscle and liver tissues. In both tissues the receptor activates Gs/PKA signaling, but glycolysis is only activated in the liver.

[37] including elevated heart rate and hypertension

Pathophysiology Related to Adrenal Hormones

Cushings's syndrome[38] is the result of elevated cortisol levels, either due to a pituitary tumor which constitutively secretes ACTH, or an adrenal tumor which constitutively secretes cortisol. In

[38] Harvey Cushing. The basophil adenomas of the pituitary body and their clinical manifestations. *Bulletin of the Johns Hopkins Hospital*, 50:157–8, April 1932. ISSN 0035-8843

either case, the consequences of over-production of cortisol are diabetes (elevated blood glucose), liver fat accumulation, muscle weakness, reduced bone mass, reduced immune function and enhanced subcutaneous fat deposition. In terms of dental physiology, the reductions in immune function often leads to periodontis and swelling of gums. Similar phenotypes can also occur with prolonged glucocorticoid treatment, for example when prescribed glucocorticoids as chemotherapeutic or anti-immune function therapies.

CONN'S SYNDROME[39] IS SIMILAR TO CUSHING'S SYNDROME in that it is due to an adrenal tumor, but in this case it is due to a tumor in the zona glomerulosa. This results in constant overproduction of aldosterone, in spite of normal angiotensin II signaling. This leads to too much salt retention, leading to high blood pressure, headaches and muscle weakness. Conn's syndrome can be treated by mineralcorticoid receptor antagonists.

[39] J W Conn and L H Louis. Primary aldosteronism: a new clinical entity. *Transactions of the Association of American Physicians*, 68:215–231; discussion, 231–233, 1955. ISSN 0066-9458

ADDISON'S DISEASE[40] is due to immune destruction of the adrenal gland, preventing steroid hormone production. In this case glucocorticoids and mineralcorticoids cannot be made and therefore patients have excessive salt excretion. Patients are prone to stress-induced hypoglycemia and low blood pressure, a condition known as an Addisonian crisis[41]. Since there is no feedback from cortisol to the CRH/ACTH axis, ACTH is hyper-produced in these patients. Elevations of ACTH are linked to elevations in another hormone called α-melanocyte stimulatory hormone[42] as they are both produced from the same transcript. Elevations in α-MSH lead to the characteristic hyperpigmentation associated with Addison's disease.

[40] Thomas Addison. *On The Constitutional And Local Effects Of Disease Of The Supra-Renal Capsules*. Samuel Highley, London, 1855

[41] Think about how you could treat Addison's disease.

[42] α-MSH

CONGENITAL ADRENAL HYPERPLASIA[43] results from loss of function mutations in the biosynthesis genes involved in the production of steroid hormones. Depending on where the mutation occurs, this prevents the synthesis of some or all of the mineralcorticoids, glucocorticoids and sex steroids. Some of the primary phenotypes are reduced development of repdroductive organs, salt wasting, and susceptibility to Addisonian crises. This genetic disorder and can often be treated pharmacologically by providing the missing steroid hormones.

[43] also known as adrenogenital syndrome

PHEOCHROMOCYTOMAS ARE DUE TO AN OVERPRODUCTION OF NOREPINEPHRINE. Pheochromocytoma are tumors that inappropriately secrete adrenaline or noradrenaline at high levels and are insensitive to the normal negative feedback mechanisms. Clinically these patients have elevated heart rate, blood pressure and anxiety

and undergo rapid weight loss and elevated blood glucose. These patients are often treated surgically[44] and with beta-blockers.

[44] to remove the tumor

In the next lecture, we will consider growth hormone, and how growth is regulated by endocrine factors during the various stages of development.
