

Basics of Neuroendocrinology

Dave Bridges, Ph.D.

March 18, 2016

The hypothalamus is the primary site of peripheral:central signal integration. The two main parts of the brain that are involved in endocrine responses are the hypothalamus and the pituitary. The hypothalamus is main point of central/endocrine integration, whereas the pituitary is the main endocrine organ under hypothalamic control. We will also discuss the hormones secreted from the posterior pituitary. This lecture will cover pages 333-339 and 508 in the textbook¹.

<i>Vasopressin</i>	5
<i>Oxytocin</i>	6

Learning Objectives

For this lecture, the learning objectives are:

- Recall anatomical, biochemical, and functional evidence showing intimate relationships between hypothalamus and pituitary.
- Describe how hormones are sensed by the neurons of the hypothalamus, and the role that the blood brain barrier and transport mechanisms play.
- Recall how the central nervous system can integrate with the hypothalamus and modify both hormonal secretions and executive function.
- Describe the differences in how hypothalamic signals are passed to the posterior and anterior pituitary glands.
- Name two major posterior pituitary hormones, their chemical category, and succinctly describe their secretory mechanism.
- Describe cellular actions of vasopressin in terms of site of actions, receptors, and cellular signals.
- Discuss briefly aquaporin water channels and relation to vasopressin.
- Predict what the changes are expected in urine volume and osmolality and in ECF volume when vasopressin synthesis or secretion is severely impaired. Predict what will happen to water intake. Explain why there can be transient diabetes insipidus following a whiplash injury, and the rationale for therapy during this time.
- Describe the control of vasopressin release.
- Describe the function of oxytocin with respect to delivery and lactation.

Anatomy of the Hypothalamus and Pituitary

The hypothalamus is unable to secrete hormones to the circulation in large amounts, so it relies on the pituitary to get hormones into the bloodstream and to communicate with the rest of the body.

The Hypothalamus

The hypothalamus is located above the midbrain but below the thalamus. It can respond to blood-borne signals because the blood-brain barrier is partially permeable in this area. Small hormones such as adrenaline, or lipid soluble hormones such as cortisol are able to permeate the barrier without assistance, but some hormones are actively transported across the blood brain barrier to reach the hypothalamus². The mechanisms of this differential permeability are not well understood, but for example, resistance to the appetite suppressive effects of leptin in obesity are thought to, at least in part, be due to reduced leptin permeability³.

FOR SUCH A SMALL ORGAN, THE HYPOTHALAMUS IS VERY ANATOMICALLY COMPLEX. The hypothalamus can be anatomically separated into several sub-regions called nuclei⁴. Each of these regions regulates a specific hypothalamic function, some of which will be covered in detail in future lectures. As an example, the suprachiasmatic nucleus (SCN) regulates circadian rhythms which are the changes that occur at approximately 24h cycles. These internal hypothalamic nuclei can communicate with each other via direct neural projections.

THE HYPOTHALAMUS CONNECTS TO SEVERAL OTHER AREAS OF THE BRAIN. In addition to its ability to communicate with the pituitary (see below), the hypothalamus also has bi-directional connections to other brain regions including the hippocampus, amygdala, and prefrontal cortex. In this way, direct neural connections between brain regions can form circuits in which internal signals, external signals and executive function can be combined.

The Pituitary

The pituitary⁵ is a small pea-sized gland that is divided into three lobes, a posterior⁶, intermediate and anterior pituitary⁷. The pituitary is located at the base of the brain, as shown in Figure 1. The anterior pituitary produces and releases several hormones including growth hormone (GH), thyroid-stimulating hormone, adrenocorticotrophic hormone (ACTH), prolactin, lutenizing hormone and follicle stimulating hormone (FSH). These are released in response to signals

⁴ no, these names will not be on the test

⁵ Named by Aelius Galenus in 200 BC as the "gland that drops slime", due to a (incorrect) role in regulating nasal mucous. Sometimes the pituitary is referred to as the hypophysis.

⁶ sometimes called the *neurohypophysis*

⁷ sometimes called the *adenohypophysis*

from the hypothalamus, which pass through a specialized capillary system called the *hypothalamic-hypophyseal portal system*. The anterior pituitary is an extension of the hypothalamus and is responsible for the release of vasopressin and oxytocin, two peptide hormones.

The Hypophyseal Portal System Connects the Hypothalamus to the Anterior Pituitary

To communicate with the *anterior pituitary*, hypothalamic neurons directly release hormones into a specialized blood vessel system called the hypophyseal portal system. Hormones travel a small distance from the hypothalamus to the anterior pituitary⁸. Here they bind to specific G-protein coupled receptors on specialized secretory cells of the anterior pituitary. Specificity in these endocrine systems is achieved by having specialized cells, with specialized receptors which only respond to specific hypothalamic hormones and only secrete one substance into the peripheral circulation. There are several examples of this system, described in Table 1.

Acronym	Pituitary Cell Type	Pituitary Hormone
CRH	Corticotropes	ACTH
GnRH	Gonadotropes	FSH/LH
TRH	Thyrotropes/Lactotropes	TSH/Prolactin
GHRH	Somatotropes	GH
SS	Somatotropes	Prevents GH

THERE ARE SEVERAL CELL TYPES in the anterior pituitary. In general these cell types are responsible for a single hormone to be released into the bloodstream. CRH (Corticotropin Releasing Hormone), GnRH (Gonadotropin Releasing Hormone), TRH (Thyrotropin Releasing Hormone), GHRH (Growth Hormone Releasing Hormone) and SS (Somatostatin) are all made by the hypothalamus and alter the release of hormones in the anterior pituitary.

The Infundibulum Connects the Hypothalamus to the Posterior Pituitary

The posterior pituitary is an outgrowth of the hypothalamus and therefore has direct neural projections from the hypothalamus. The anatomical structure connecting the hypothalamus to the posterior pituitary is called the infundibulum⁹. The neurons in this region begin in the hypothalamus, but rather than releasing a neurotransmitter into a synapse, they directly release their hormones from their axons into the circulation.

Figure 1: The location of the pituitary.

⁸ These hormones are therefore at extremely low levels in the peripheral circulatory system and difficult to detect.

Table 1: Hormones which use the hypophyseal portal system.

⁹ This stalk is somewhat fragile and can be broken during trauma such as whiplash

The Hormones of the Posterior Pituitary

We will discuss some of the roles of the anterior pituitary hormones in the next two lectures¹⁰. For the remainder of this lesson we are going to focus on the two hormones released from the posterior pituitary.

Vasopressin

Vasopressin¹¹ regulates osmolality in the blood¹². Vasopressin is a small peptide hormone, with 9 amino acids. Water retention is important for two aspects, one is to maintain a normal blood volume, and the other is to maintain appropriate salt balance. Vasopressin senses *volume and osmolality* and regulates water re-uptake in the kidney. Elevated osmolality (too much salt in the blood) is sensed by osmoreceptors in the paraventricular nuclei and supraoptic nucleus of the hypothalamus. Osmotic status is also sensed by other regions of the brain with permeable blood brain barriers such as the subfornicular organ, which then projects to the vasopressin releasing neurons in the hypothalamus. Alternatively, a *decrease* in blood volume can be detected by mechanoreceptors in the carotid sinus, which also project to the vasopressin-releasing neurons. Once the vasopressin-secreting neurons are activated by one of these stimuli, these neurons release vasopressin into the blood stream.

VASOPRESSIN IS SENSED PERIPHERALLY BY 4 RECEPTORS. The most important of these is AVPR2, which is a G_s-linked GPCR in the collecting ducts of the kidney. This cascade activates PKA-mediated exocytosis of AQP2¹³ containing vesicles, increasing the amount of AQP2 at the plasma membrane. This allows for more water to be transported back from the collecting ducts into the blood. This increases blood volume and decreases salt concentration. This process is summarized in Figure 2. An additional role of vasopressin is to cause modest vasoconstriction in the vasculature. This occurs to reduce blood flow in the case that reduced blood volume is due to trauma. A third location for vasopressin receptors is the anterior pituitary, where the corticotrope cells have AVPR1B or AVPR3 receptors, which initiate ATCH/cortisol-dependent stress responses.

THERE ARE SEVERAL DISORDERS ASSOCIATED WITH ABBERANT VASOPRESSIN SIGNALING. Lack of vasopressin results in hypernatremia¹⁴ and diabetes insipidus¹⁵. This can be due to either lack of vasopressin production, or lack of response to vasopressin in the kidneys. On the other hand, too much vasopressin signaling¹⁶ can result

¹⁰ Sex hormones and the thyroid/parathyroid hormones will be discussed by Drs. Parfenova and Parthasarathi

¹¹ occasionally called ADP (antidiuretic peptide), ADH (antidiuretic hormone), or argipressin

¹² See Dr. Tigyi's lectures for more information on osmolality

¹³ an aquaporin, or water transporter

Figure 2: The role of vasopressin in kidney collecting ducts.

¹⁴ Elevated salt concentration in blood.

¹⁵ thirst and release of excessive amounts of urine, not to be confused with diabetes mellitus which is a disorder of blood glucose levels.

¹⁶ sometimes by a vasopressin-secreting tumor, or in response to nephrotic syndrome

in hyponatremia. This is often treated by vasopressin antagonists.

Oxytocin

Like vasopressin, oxytocin is a peptide hormone released from the posterior pituitary. The mechanisms which signal its release are not very well understood, but they involve synaptic activation of these neurons in the PVN of the hypothalamus. In response to these signals, oxytocin is secreted at the posterior pituitary into the blood stream.

THE BEST CHARACTERIZED ROLE OF OXYTOCIN IS DURING DELIVERY. The uterine wall responds to elevations in oxytocin to induce contractions. Sensory neurons detect these contractions and project directly back to the brain where they synapse with the oxytocin-releasing neurons. This causes more oxytocin release and therefore forms a *positive feedback loop* known as the Ferguson reflex¹⁷.

Another role of oxytocin is in the release of milk at mammary glands. Oxytocin release stimulates contraction of the smooth muscle that lines the mammary alveoli releasing the milk into the mammary ducts. In this manner it works alongside prolactin¹⁸ to ensure proper production and release of milk. Less well understood is the effects of oxytocin on mood and behavior. Oxytocin has been linked to enhanced feelings of trust, social interactivity and bonding through neuroendocrine mechanisms that are just being explored now.
